ABSTRACT

The International Pacific Halibut Commission, recognizing a need for standardized data that were independent of the commercial fishery, conducted surveys with setline gear on a pre-determined pattern of stations from 1963 through 1966. The survey design was reviewed and modified surveys were undertaken from 1976 through 1979. This report documents the objectives and design of the surveys and presents detailed information on tags released and recovered, as well as data on catch per unit effort, size, age and sex of halibut. A summary of the catch of species other than halibut also is provided.

Halibut Assessment Data: Setline Surveys In The North Pacific Ocean, 1963-1966 And 1976-1979

by

Stephen H. Hoag, Gregg H. Williams,
Richard J. Myhre, and Ian R. McGregor

INTRODUCTION

The International Pacific Halibut Commission (IPHC) has relied on data from the commercial fishery to assess populations of Pacific halibut (*Hippoglossus stenolepis*) and regulate the fishery. Data from fishermen's log books provide estimates of catch per unit effort (CPUE); data from landings produce estimates of the size and age of halibut in the catch. IPHC has also conducted research operations on chartered vessels, but these research cruises usually resembled commercial operations in that most of the fishing occurred on specific grounds rather than over broad areas.

Reliance on the commercial fishery as a primary source of data for stock assessment has certain limitations. Because the fleet concentrates fishing effort in specific areas, the data collected from the fishery are not necessarily representative of the entire halibut population. The fleet periodically changes its operation and fishing techniques; changes in bait, hook-spacing, soak-time, and navigational equipment may alter the efficiency of the gear, and thus affect estimates of CPUE (Skud 1972, 1978, Hamley and Skud 1978). Another change occurred when IPHC increased the minimum size limit in 1973. Vessels shifted fishing grounds, causing changes in CPUE, age, and size that did not represent changes in the stocks. Finally, samples of commercial landings do not provide data on sex composition. The lack of information on sex composition has hampered assessment of halibut stocks because mortality and growth differ between males and females. In short, although data from the commercial fishery have been and will continue to be useful, an independent source of data reduces the chance of errors in the assessment of halibut populations.

IPHC, recognizing this need, conducted several surveys during the early and mid-1960's. Some of the surveys employed trawl gear and monitored populations of juvenile halibut or assessed the potential effect of a trawl fishery on halibut. Results from these surveys have been published (e.g., IPHC 1964, Best 1970), but are of limited value in assessing adult halibut populations because trawl gear is selective for small halibut (Myhre 1969).

Much of the Northeast Pacific Ocean was surveyed with setline gear, and resultant data serve as a base for assessing adult stocks. The survey entailed fishing about 1,000 stations on a predetermined pattern from 1963 to 1966. Although tagging was the primary objective of the survey, the value of the program for providing size, age, and sex data was recognized (IPHC 1966). The underlying basis for the survey was that systematic sampling of an area would provide a better representation of the total population than sampling commercial concentrations.

The need for stock assessment data, independent of the fishery, became apparent again during the 1970's (Hoag 1976). Having reviewed various sampling designs, IPHC concluded that a system similar to the original 1963-1966 survey was satisfactory. However, several modifications to the original survey were made: the number of stations and size of the sampling area were reduced, and fishing procedures were

more rigidly standardized. This modified survey was initiated in 1976 and continued annually during 1977-1979.

Results from the "assessment surveys" should be useful for a wide variety of population studies, but with the exception of preliminary findings given in various IPHC Annual Reports, the results have not been published. The purposes of this report are to document the objectives and design of the 1963-1966 and 1976-1979 surveys, and summarize data in sufficient detail to provide a base for future analyses.

SAMPLING DESIGN

The sampling design was largely dictated by the distribution of fish and logistical considerations. Sampling occurred during the summer, when halibut are distributed over the continental shelf at depths of less than 250 fathoms (about 450 m) and weather is favorable. Meaningful stratification of the sampling area was not practical because halibut tend to concentrate in small irregular groups which are often transient. Systematic sampling was chosen rather than random sampling to ensure coverage of the area and to allow for standardizing setting and hauling times during the operation.

Two predetermined patterns of stations were established: the first in the western Gulf of Alaska; the second in Hecate Strait and Queen Charlotte Sound, British Columbia (Appendix Figures 1 and 2). The station pattern was a modification of that used in IPHC's trawl survey in 1961 through 1963 (IPHC 1964). Stations off Alaska were arranged along parallel north-south transects, 12 nautical miles (22.2 km) apart, running outward from the shoreline to a depth of 250 fathoms; the stations were located every 6 nautical miles (11.1 km) along these transects. A similar procedure was used off British Columbia, except that the transects ran east-west. A station pattern also was developed for the eastern Gulf of Alaska, but fiscal limitations prevented a survey of that area.

Nearly all of the stations shown in Appendix Figures 1 and 2 were fished once during the 1960's. The Portlock-Albatross grounds outside of Kodiak Island (transects 41 to 53) were sampled in 1963; Shelikof Strait (inside of Kodiak Island, transects 51 to 58) and the Chirikof region (transects 53 to 69) were sampled in 1964; part of Hecate Strait including Queen Charlotte Sound (transects 1 to 14) and the Shumagin region (transects 67 to 95) were sampled in 1965; and the remainder of Hecate Strait (transects 12 to 21) was sampled in 1966. In Alaskan regions the sampling each year was split into two segments. Stations on even-numbered transects were sampled early in the summer and stations on odd-numbered transects were sampled later in the summer. This procedure provided information on changes in the distribution of halibut during the summer.

The design of the recent surveys (1976-1979) differed from the early surveys: the area and number of stations within the area were reduced, and the survey was repeated annually. Sampling areas were restricted to the Portlock-Albatross grounds in the Kodiak region and Hecate Strait-Queen Charlotte Sound in the Charlotte region, which produce nearly half of the total catch by the commercial fishery. The number of stations was reduced to approximately 100 in each area by sampling every other transect: odd-numbered transects 41 through 53 in the Portlock-Albatross area and odd-numbered transects 3 through 19 in Hecate Strait-Queen Charlotte Sound.

Fishing procedures were similar on both the early and recent surveys, but were more rigidly standardized in the latter surveys. Usually, 8 skates of gear were fished at each station, and 4 stations were sampled each day. The gear usually was fished along the transect line through each station, but occasional adjustments were necessary because of conflicts with other fishing vessels or logistical considerations. For the recent surveys, the gear was set between 0500 and 0700 hours, and hauling at the four stations began at 1000, 1300, 1600 and 1900 hours, respectively. Three types of bait (salmon, herring, and cod) were varied uniformly among hooks on each skate, i.e., each bait was used on every third hook. The hook-spacing and length of the skates varied among surveys, but the differences were accounted for by estimating the effective effort on each station, based on Skud's (1972) study.

All of the halibut in the catch were measured (fork length) and those without serious injuries (usually about 50% of the total) were tagged. The remainder were used to estimate age and sex. The halibut catch was recorded by station and skate in the recent surveys, but only by station in the earlier surveys. The number and weight of species other than halibut were only recorded since 1977.

Several deviations from the sampling design have occurred because of fiscal or navigational problems: (1) The 1976 survey was limited to 24 stations in the Kodiak region and 80 stations in the Charlotte region, (2) Only 94 stations were fished in the Kodiak region in 1977, and (3) The Charlotte region was not surveyed in 1979.

The following table provides an inventory of the various surveys by year, region, and vessel, along with a summary of sampling effort and the halibut catch.

Year	Region	Vessel	Period of Operation	No. of Stations Fished	No. of Standardized Skates		Halibut Catch	
					Number	Pounds	Number	Pounds
1963	Kodiak	ECLIPSE	May-August	248	2090.40	5,955	188,487

DATA SUMMARIES

Data from each station, grouped by year and sampling area, are summarized in the Appendix.

Table 1 shows the CPUE of male and female halibut and their average weight for ages 2 through 25+ years. Table 2 gives the CPUE of males and females by 5 cm length interval from 30 cm to 200+ cm. CPUE is the number of fish per standard skate, which is defined as 1,800 feet (550 meters) of groundline with 100 hooks attached at 18-foot (5.5 meter) intervals. Average weight is in pounds (head-off, eviscerated) and was estimated from the length of individual fish using a previously established length-weight relationship.¹ IPHC traditionally has used metric measurements for fish length and English measurements for fish weight. This apparent inconsistency is continued in this report because most investigators are familiar with halibut data in this form.

The length of every halibut was available, but age and sex were known only for those fish unsuitable for tagging. The sex composition of the total catch was estimated from the proportion of males and females in each 5 cm length interval. Treating each sex separately, we projected the total number of fish at each age using the method described by Hardman and Southward (1965).

The estimated age and sex composition of the total catch could be biased because the fish sampled for age and sex information were not randomly selected and may not have the same length composition as those that were tagged. However, the likelihood of bias is small because the age and sex compositions were estimated for each 5 cm length interval and then projected to the total number of fish in the interval. Hence, bias would result only if the sex-age-length relationships differed between the sampled and the tagged fish, but not if the length compositions alone differed. Note also that setline gear is selective for large fish (Myhre 1969), so small and young fish were underrepresented in the catch, relative to the population.

Table 3 gives the number of tagged fish released by 5 cm length interval and tag type. Data from each tag recovery are listed in Table 4 by region, month, and year of release. Several types of tags were used in the early surveys: two types of strap tags (Monel and stainless steel), a wire-spaghetti tag, loop tag, and a dart tag. In many cases, two types of tags were placed on the same fish.

Several factors affect the rate of tag recovery. Tag shedding and non-reporting losses vary with tag type (Myhre 1966), and various tag types were not used representatively with respect to size of fish or region of release. The introduction of a premium tag reward in 1966 may have reduced non-reporting losses; under this program \$100.00 rewards were paid for randomly selected tags (IPHC 1973). The size composition of the tag recoveries and the non-reporting loss varies with the type of gear. Domestic setlines, selective for large fish, returned most of the tags. Foreign and domestic trawls, selective for small halibut, catch large numbers of halibut (Hoag and French 1976), but report relatively few tags; hence, a high non-reporting loss is likely.

Information on recovered tags is often incomplete and may occasionally be erroneous. For example, sex and maturity is usually not determined because fishermen eviscerate halibut at sea, and external sex characteristics have not been identified. Some tags are not found until after the fish has been unloaded and processed on

¹/W = (6.9205392 x 10⁻⁶)L^{3.24} where W = net weight (head-off, eviscerated) in pounds and L = fork length in centimeters (IPHC, unpublished).

shore, and therefore, provide little information. IPHC personnel measure the length of each fish recovered whenever possible, but at times, length data are available only from the finder. Errors undoubtedly exist because changes in length from release to recovery are occasionally negative or excessively large.

Table 5 provides the CPUE (number of fish per standard skate) and average weight of species or species groups other than halibut caught during the surveys in 1977 through 1979. The average weight estimates are based on a subsample of approximately 10 individuals at each station fished. Length frequency data also were collected for these species, but were too meager to include in the data summary.

ACKNOWLEDGEMENTS

The fishermen and staff who collected these data made this report possible. Although they are too numerous to mention, we acknowledge their efforts. We thank Keith S. Ketchen, Loh-Lee Low and James Balsiger for reviewing the manuscript. We also thank Raymond E. Walden for his assistance in preparation of the appendix tables.
